

Some Clarifications and Recommendations on Fit Indices

Your readings (West, Taylor, and Wu, 2012; Hu & Bentler, 1999; Kline, 2016) and others distinguish between types of fit indices, sometimes using terms such as *absolute fit indices*, *relative (or comparative) fit indices*, *parsimony fit indices*, and those based on the *noncentrality* parameter (for good overviews and computational details for fit indices, see also Hu & Bentler, 1998; Maruyama, 1998; Tanaka, 1993). Below I attempt to provide a simplified overview of some of the better-known SEM fit indices to help make sense of the dizzying array of model fit measures. I include a considerable number of professional opinions, which I know that not all SEM experts necessarily agree with, but I believe the views presented are shared by most SEM users and are a reasonable representation of the current standards of practice.

Absolute Fit Indices (χ^2 , GFI, AGFI, Hoelter's CN, AIC, BIC, ECVI, RMR, SRMR)

Absolute fit indices do not use an alternative model as a base for comparison. They are simply derived from the fit of the obtained and implied covariance matrices and the ML minimization function. Chi-square (χ^2 , sometimes referred to as T) is the original fit index for structural models because it is derived directly from the fit function $[F_{ML}(N-1)]$. Because chi-square is the original fit index and because it is the basis for most other fit indices, it is routinely reported in all SEM results sections.

In practice, however, chi-square is not considered to be a very useful fit index by most researchers,¹ because it is affected by several factors. (1) Chi-square is affected by sample size—larger samples produce larger chi-squares that are significant even with very small discrepancies between implied and obtained covariance matrices (perhaps accurate but trivial in some instances). On the other hand, small samples may be too likely to accept poor models (Type II error). Based on my experience, it is difficult to get a nonsignificant chi-square (indicative of good fit) when samples sizes are much over 200 or so. (2) Chi-square is affected by model size, in which models with more variables tend to have larger chi-square values. (3) Chi-square is affected by the distribution of variables. Highly skewed and kurtotic variables increase chi-square values. This has to do with the multivariate normality assumption that we will discuss later in the class (and is often addressable). (4) There may be some lack of fit because of omitted variables. Omission of variables may make it difficult to reproduce the correlation (or covariance) matrix perfectly. See West and colleagues (2012) for a more thorough background on the limitations of chi-square and key references.

There are several other indices that fall into the category of absolute indices, including the Goodness-of-fit index (GFI; and Steiger's, 1989, modified version known as gamma-hat or $\hat{\gamma}$), the adjusted goodness of fit index (AGFI), the χ^2/df ratio (sometimes called "normed chi-square"), Hoelter's CN ("critical N"), Akaike's Information Criterion (AIC), the Bayesian Information Criterion (BIC), the Expected Cross-validation Index (ECVI), the root mean square residual (RMR), and the standardized root mean square residual (SRMR). Most of these indices, with the possible exception of the SRMR, have similar problems to those of the chi-square, because they are simple transformations of chi-square. As one example, the AIC (as given by Tanaka, 1993) is just $\chi^2 + 2(p)$, where p is the number of free parameters (the number counted in calculating df).

Relative Fit Indices (IFI, TLI, NFI)

Relative fit indices compare a chi-square for the model tested to one from a so-called *null model* (also called a "baseline" model or "independence" model). The null model is a model in which all measured variables are uncorrelated (there are no latent variables). The null model should always have a very large chi-square (poor fit). Although other baseline models could be used, this is not often seen in

¹ A small minority of statisticians hold strongly to a philosophy that significant chi-square values indicate unacceptable fit and that a model with a significant chi-square is incorrect and requires correction or should be discarded (see Hayduk, Cummings, Boadu, Pazderka-Robinson, & Boulianne, 2007, for an introduction to this viewpoint). Thus, the argument is that relative fit indices are not valuable in research and should not be used. The vast majority of researchers, statistical researchers or applied researchers, do not hold appear to hold this view, however, because nearly all published articles report alternative measures of fit. Most researchers appear to consider models with departures from perfect fit that are small in magnitude (e.g., high relative fit indices) to remain tenable and of utility.

practice.² There are several relative fit indices, including Bollen's Incremental Fit Index (IFI, also called BL89 or Δ_2), the Tucker-Lewis Index [TLI, Bentler-Bonett Nonnormed Fit Index (NNFI or BBNFI), or ρ_2], and the Bentler-Bonett Normed Fit Index (NFI).³ Most of these fit indices are computed by using ratios of the model chi-square and the null model chi-square, taking into account their degrees of freedom. All of these indices have values that range between approximately 0 and 1.0. Some indices are "normed" so that their values cannot be below 0 or above 1 (e.g., NFI, CFI described below). Others are considered "nonnormed" because, on occasion, they may be larger than 1 or slightly below 0 (e.g., TLI, IFI). An earlier convention used above .90 as a cutoff for good fitting models, but there seems to be some consensus now that this value should be increased to approximately .95 (based largely on Hu & Bentler, 1999).

Parsimonious Fit Indices (PGFI, PNFI, PNFI2, PCFI)

Parsimony-corrected fit indices are relative fit indices that are adjustments to most of the fit indices mentioned above. The adjustments are to penalize models that are less parsimonious, so that simpler theoretical processes are favored over more complex ones. The more complex the model, the lower the fit index. Parsimonious fit indices include PGFI (based on the GFI), PNFI (based on the NFI), PNFI2 (based on Bollen's IFI), PCFI (based on the CFI mentioned below). Mulaik and colleagues (1989) developed a number of these. Although many researchers believe that parsimony adjustments are important, there is some debate about whether or not they are appropriate. I see parsimony-adjusted relative fit indices used infrequently in the literature, so I suspect most researchers do not favor them. My own perspective is that researchers should evaluate model fit independent of parsimony considerations, but evaluate alternative theories favoring parsimony. With such an approach, we would not penalize models for having more parameters, but if simpler alternative models seem to be as good, we might want to favor the simpler model.

Noncentrality-based Indices (RMSEA, CFI, RNI, CI)

The concept of the *noncentrality parameter* is a somewhat difficult one. The rationale for the noncentrality parameter is that our usual chi-square fit is based on a test that the null hypothesis is true ($\chi^2 = 0$). This gives a distribution of the "central" chi-square. Because we are hoping *not* to reject the null hypothesis in structural modeling, it can be argued that we should be testing to reject the alternative hypothesis (H_a). A test that rejected the alternative hypothesis, H_a , would make statistical decisions using the "noncentral" chi-square distribution created under the case when H_a is assumed to be true in the population (i.e., an incorrect model in the population). This approach to model fit uses a chi-square equal to the *df* for the model as having a perfect fit (as opposed to chi-square equal to 0). Thus, the noncentrality parameter estimate is calculated by subtracting the *df* of the model from the chi-square ($\chi^2 - df$). Usually this value is adjusted for sample size and referred to as the rescaled noncentrality parameter:

$$d = \frac{\chi^2 - df}{N - 1}$$

A population version is often referred to as δ and is computed by dividing by N rather than $N - 1$.

Noncentrality-based indices include the Root Mean Square Error of Approximation (RMSEA; not to be confused with RMR or SRMR), Bentler's Comparative Fit Index (CFI), McDonald and Marsh's Relative Noncentrality Index (RNI), and McDonald's Centrality Index (CI; 1990 called Mc by Hu and Bentler).

² The uncorrelated null model is not fully universal, although nearly so. Mplus uses an alternative null model (which they refer to as the "baseline" model) whenever there are exogenous measured variables (the different computation is not used for exogenous latent variables). When unanalyzed correlations among non-latent exogenous variables are included, the correlations are exempted from the parameter count in the null model, which has a conservative effect on the relative fit of the model. Most of the time this does not have a large impact on relative fit, but keep in mind that if you use a large number of measured covariates, fit may suffer. Researchers can always test a separate null model in which all variables uncorrelated (by omitting all model statements) and then compute the relative fit indices manually. Although Mplus employs this alternative definition of the baseline model, to the best of my knowledge, all other SEM software programs, except *lavaan* use a null model with all variables uncorrelated. *lavaan*, however, uses the traditional null model if all of the unanalyzed correlations are specified in the model.

³ This list excludes fit indices which use explicit parsimony corrections—see next section.

Because the noncentrality parameter is simply a function of chi-square, df , and N , several of the formulas for the relative fit indices described above can be algebraically manipulated to include the noncentrality parameter. For example the TLI can also be stated as:

$$TLI = \frac{(d_0 / df_0) - (d_{model} / df_{model})}{d_0 / df_0}$$

Where d_{model} and df_{model} are the noncentrality parameter and the degrees of freedom for the model tested and d_0 and df_0 are the noncentrality parameter and df for the null model. Work by Raykov (2000, 2005) shows that noncentrality parameter sample estimates are biased and that this problem may affect fit indices computed based on noncentrality (e.g., the RMSEA, CFI).

Sample Size Independence

Many of the relative fit indices (and the noncentrality fit indices) are affected by sample size, so that larger samples are seen as better fitting (i.e., have a higher fit index value). Bollen (1990) made a useful distinction between fit indices that can be shown to explicitly include N in their calculation and those that are dependent on sample size empirically. That is, even though a fit index may not include N in the formula, or even attempt to adjust for it, it does not mean that the fit index will really turn out to be independent of sample size. He also showed that the TLI and IFI are relatively unaffected by sample size (see also Anderson & Gerbing, 1993; Hu & Bentler, 1995; Marsh, Balla, & McDonald, 1988).

$$TLI = \frac{\chi^2_{null} / df_{null} - \chi^2_{model} / df_{model}}{\chi^2_{null} / df_{null} - 1}$$

$$IFI = \frac{\chi^2_{null} - \chi^2_{model}}{\chi^2_{null} - df_{model}}$$

This is one reason why I tend to favor Bollen's IFI. If you are interested in adjusting for parsimony, you might consider the Mulaik and colleague's index PNFI2, which is a parsimony adjusted version of the IFI. One can make an argument about parsimony adjustment similar to Bollen's argument about sample size. It might be important to differentiate between fit indices that are explicitly adjusting for parsimony and ones that are empirically affected by model complexity. The TLI is an example of an index that adjusts for parsimony, even though that was not its original intent.

Recommendations

Every researcher and every statistician seems to have a favorite index or set of indices. You should be prepared for reviewers to suggest the addition of one or two of their favorite indices. These suggestions are fairly easy to accommodate by the addition of the indices they suggest, but it would not be fair to yourself or others to pick the index that is most optimistic about the fit of your model. Since the late 1990s, there has been concern that the recommended cutoff values for relative fit indices of .90 are too low and that higher values, such as .95 should be used. The simulation by Hu and Bentler (1999) seems to have been instrumental in moving the standards toward a more stringent criterion as well as nudging modelers to more consensus on which fit indices to report.

Hu and Bentler (1999) empirically examine various cutoffs for many of these measures, and their data suggest that to minimize Type I and Type II errors under various conditions, one should use a combination of one of the above relative fit indexes, such as the CFI or IFI, with values greater than approximately .95, in combination with the SRMR (good models < .08) or the RMSEA (good models < .06). These values should not be written in stone, and there may be models that don't quite reach these values and for which there are no better alternatives and for which there do not seem to be theoretically sensible improvements possible. There have been some valid concerns raised about circumstances in which they do not perform optimally (e.g., Fan & Sivo, 2005; Marsh et al., 2004), so the cutoffs proposed are not perfect. In my experience of testing a wide range of models, however, I have found that these

cutoff values tend to be reached when a) a model cannot be substantially improved with theoretically sensible model modifications; b) a measurement model has high standardized loadings, fits better than alternative measurement models with different number of factors, and has no evident theoretically sensible modification indices; c) a full structural model does not have any alternative models that have superior fit. So, although the cutoffs recommended by Hu and Bentler may not be infallible or universally applicable, they appear to me to be useful for evaluating a large number of models in practice, and I presume this is why these cutoffs have remained a fairly widely applied standard of practice for some time now.

Comment: Hu and Bentler's work did much to help narrow the field of fit indices and increase the standards for model fit. Their recommendations do not revolve around any single index, and it seems many indices are effective for screening poor models. Their recommendations involve using one of the relative fit indices close to .95 or higher—either CFI, IFI, RNI, or gamma hat or Mc (McDonald, 1989) with a .90 cutoff—in combination with one of the two absolute fit indices—either RMSEA or SRMR—above around .08 or .06, respectively. They also report high intercorrelations among many fit indices, so none may have an enormous advantage over others. Hu and Bentler found that Mc, TLI, and RMSEA tend to be too conservative in selecting models (more likely to so how poor fit) in small samples, so I usually do not use RMSEA unless reviewers ask for it and I have a slight preference for Bollen's IFI index based on Bollen's argument (Bollen, 1990) and the data from Hu and Bentler suggesting that the IFI is not importantly affected by sample size. I would ideally prefer to report the IFI in combination with the SRMR for my work, but because Mplus computes only a limited number of fit indices and does not include the IFI, I tend to report the CFI instead (for the many examples that I have computed IFI for by hand, I have found a close correspondents with the CFI anyway). An important point is that researchers should decide a priori about fit criteria, state those criteria in their reports, and consider reporting more than one fit index (Jackson, Gillaspay, & Purc-Stephenson, 2009). It is not fair to change fit indices based on values that make your fit look better!
