SYMBOLIC DYNAMICS AND ROTATION NUMBERS

Peter VEERMAN

Received 12 June 1985

In the space of binary sequences, minimal sets, that is: sets invariant under the shift operation, that have no invariant proper subsets, are investigated. In applications, such as a piecewise linear circle map and the Smale horseshoe in a mapping of the annulus, each of these sets is invariant under the mapping. These sets can be assigned a unique rotation number equal to the average of the number of ones in the sequences.

One special minimal set is the optimal set for which the convergence of the running average to the rotation number is faster than for any other minimal set. These sequences are instrumental in analytically solving for the width of the parameter intervals for which members of a one parameter family of piecewise linear critical circle maps have rational rotation number.

1. Introduction

In the study of nonlinear maps and flows, aspects of complicated behavior can often be described in terms of symbolic dynamics. In this approach, the action of the mapping restricted to an appropriate subset of the domain, is shown to be conjugate to a subshift on a set of sequences of finitely many symbols\(^1\). The simplest case is the full shift on the space \(\{0, 1\}^\mathbb{Z}\) of two symbol sequences, which arises, for example, in the study of Smale's horseshoe map\(^2\).

In this study we shall work in the space \(S\) of bi-infinite sequences of ones and zeros. We equip the space with the norm \(\Sigma_{n=0}^{\infty} i_n/2^n\) where \(i_n\) are the digits of an element \(s\) of \(S\). This metric induces one to establish an isometry of \(S\) to the set of pairs of real numbers \((x, y) \in [0, 1) \times [0, 2)\):

\[
x = \sum_{n=0}^{\infty} \frac{i_n}{2^n}, \quad x \in [0, 1),
\]

\[
y = \sum_{n=0}^{\infty} \frac{i_n}{2^n}, \quad y \in [0, 2) \quad \text{(includes } \frac{i_0}{2})
\]

With the given metric corresponds to the rectangle $[0, 1] \times [0, 2]$ equipped with the induced "Manhattan"-metric (the sum of the $x$ and $y$ distances rather than the root of the squares of the sums). $S$ is then obviously a connected space because the rectangle is connected. When later on we consider one-sided sequences we shall prove that the sets we are interested in project one-to-one onto the $x$-axis, so that we can identify bi-infinite sequences with semi-infinite ones.

Let $\sigma$ denote the shift operation, i.e.

$$\sigma(s) = \sigma(\ldots i_{-2}i_{-1}i_0 \cdot i_1 i_2 \ldots) = \ldots i_{-1}i_0 \cdot i_1 i_2 \ldots \ldots .$$

We propose to study sets minimal with respect to the shift. A minimal set is a closed set which is invariant under the transformation of interest and which contains no proper subset with the same properties. The minimal sets we consider can be assigned a "rotation-number", $\rho$, defined as follows. Let $\rho_n(s) = (1/n) \sum_{i}^{n} i_n$, then we consider sets for which the following limits exist and have the same value:

$$\lim_{n \to \infty} \rho_n(s) = \lim_{n \to \infty} \rho_n(s) = \rho(s);$$

$\rho(s)$ is simply the average number of ones in the sequence. These minimal sets turn out to be Cantor sets in the space of sequences. (A Cantor set is a closed, perfect and totally disconnected set.)

The reason for calling the quantity $\rho$ a rotation-number is that in applications it corresponds to the usual rotation-number. In Hockett and Holmes' the authors consider a Poincaré section of the Josephson junction equation which defines a mapping on the two-dimensional annulus. They prove that, in a certain parameter-range, there is a transversal interaction of stable and unstable manifolds giving rise to a Smale horseshoe. Restricted to the horseshoe, the mapping is conjugate to the shift. They then show that the average number of ones (if this limit exists) of a sequence $s$ corresponding to point $x$ in the horseshoe is a very simple manner related to the rotation-number of $x$ under the Poincaré map. Minimal sets with rotation-number $\rho$ in $S$ represent minimal sets in the horseshoe under the Poincaré map.

In this paper we extend their use of symbolic dynamics in the study of rotation-numbers and indicate applications to invariant sets of a piecewise linear analogue of a critical circle map.

In section 2 we start by constructing a specific minimal set for each irrational number $\rho$ (the number $\rho$ will denote an irrational number throughout this work, unless otherwise mentioned), called the optimal set $\Sigma_\rho$. This is the minimal set for which the running averages $\rho_n$ converge faster to $\rho$ than for any other minimal period $\rho$. Under such orbits have the.

In section 3 we construct Cantor sets similar to a monotone.

In section 4 related to sequences of $\rho$, we

$$\rho = \frac{1}{\beta_1}$$

This construction is self-similar. Some of the irrational data are

In section 5 the complex angle $x = 2x$, mod 1), all the min interval $[\beta/\rho]$

We then take (see fig. 1) a piece with d
other minimal set. The sequences in $\tilde{S}_\rho$ exhibit great regularity. Although non-periodic, each finite subsequence in $s \in \tilde{S}_\rho$ reappears infinitely often. In this section we develop a geometrical algorithm for generating all the elements of $\tilde{S}_\rho$.

Under certain conditions, these sequences correspond to the “order-preserving orbits” constructed by Hockett and Holmes$^4$ (i.e., the points on each orbit have the same relative ordering as the orbit of a point under rigid rotation).

In section 3 we prove that the optimal sets are minimal sets as well as Cantor sets in $\mathcal{S}$. The proofs are quite general and apply also to the other “non-optimal” examples of minimal sets that we give in this section. In one example, we construct for each irrational $\rho$ uncountably many minimal sets, all of which are Cantor sets. This result also carries over to the example of Hockett and Holmes: for each rotation-number $\rho$ there are uncountably many minimal Cantor sets in the horseshoe. The other example we give is a construction very similar to Aubry’s construction of minimal energy orbits for area preserving monotone twist maps of the annulus$^5$.

In section 4 it is argued that the construction of sequences in $\tilde{S}_\rho$ is intimately related to the theory of continued fractions. It is proven that some of the sequences in $\tilde{S}_\rho$ can be constructed from the continued fraction coefficients $\beta_i$ of $\rho$, where

$$\rho = \frac{1}{\beta_1 + \frac{1}{\beta_2 + \cdots}}.$$

This construction is entirely symbolic, i.e.: it consists of concatenating finite subsequences without doing any calculations. The sequences we obtain this way are self-similar, non-periodic sequences, self-repeating on every length-scale. Some of the sequences constructed in this fashion turn up quite naturally in an irrational decimation procedure of a path-integral$^6$.

In section 5 we work out a particular application of optimal strings. Consider the complex map $f : z \to z^2$ restricted to the unit-circle $|z| = 1$ parametrized by the angle $x = (1/2\pi) \arg(z)$ (this is simply the angle-doubling map: $\theta : x \to 2x, \text{mod } 1$). Then, writing $x$ as a binary number, $\theta$ is just the shift map. Among all the minimal sets under $\theta$, the only ones that are contained in a closed interval $[\beta/2, \beta/2 + 1/2]$ for some $\beta \in [0, 1]$ are the optimal sets $\tilde{S}_\rho$ for irrational $\rho$.

We then modify the map $\theta$ by mapping the complement of this interval to $\beta$ (see fig. 1) and call the resulting “cut-off” map $\phi_\beta$. The piecewise linear map $\phi_\beta$ is now a degree on $\tilde{S}_\rho$. It is an analogue of a critical map in that it has a piece with derivative zero (fig. 12). For the family $\phi_\beta$, we work out exactly the
length of the locking intervals (the intervals in parameter space where \( \phi_\rho \) has periodic orbits) using the properties of optimal sequences. This result is then generalized to apply to degree one mappings \( \phi_{\epsilon, \rho} \) obtained in a similar manner from

\[
\theta \tau x \rightarrow \tau x \mod 1
\]

where \( \tau \) is an arbitrary real number greater than one. In addition to this we find the exact representation of the invariant attracting set \( \phi_{\epsilon, \rho} \) for all rotation numbers. In Kadanoff\(^7\) and Boyland\(^8\) a similar "cut-off" map is used to obtain information about orbits in a supercritical map.

Finally in this introduction we give the notation for equivalence-classes that we will use. In \([0, 1)\) an equivalence relation is defined by \( \sim \):

\[
x_1 \sim x_2 \text{ iff } x_1 = (k \rho + x_2) \mod 1, \quad k \in \mathbb{Z}.
\]

The equivalence-classes

\[
\{x | x = (d + k \rho) \mod 1 | k \in \mathbb{Z}\}
\]

are denoted by \([d]\), so that for instance \([\rho]\) includes the number 0.

In \((0, 1]\) the equivalence is defined similarly. The only relevant distinction to make is that now 1 is an element of \([\rho]\), whereas 0 is not in the interval. This distinction plays a role in proving some of the results (lemma 3.4).

The number \( \rho \) is fixed and irrational throughout the paper except in section 5 where it is being varied.

2. The optimal sets

In this section we address the question of constructing sequences for which the running rotation number \( \rho_n(s) \) approaches its limit as fast as possible...
SYMBOLIC DYNAMICS AND ROTATION NUMBERS

547

(optimal sequences). The sequences will in fact be such that, for every k, \( \rho_k (a^k s) \) approaches its limit as fast as possible. The construction has a very geometrical flavor to it.

A way of visualizing sequences is the following. For each \( n \in \mathbb{Z} \) pick integers \( p_n \) that satisfy (fig. 2)

\[
i_n = p_n - p_{n-1}, \quad i_n \in \{0, 1\}
\]

and \( i_n \) are the digits of the sequence \( s \). Note that \( p_n - p_0 \) gives the number of ones in the digits 1 through \( n \) (for negative \( n \): \( -p_n - p_0 \) gives the number of ones in the digits \( n + 1 \) through 0). In what follows \( p_0 \) will always be equal to zero. The running rotation number \( \rho_n (s) \) is simply the tangent of the line through the origin and \( (n, p_n) \) (see fig. 2):

\[
\rho_n (s) = \frac{p_n}{n}.
\]

The question that arises first is: which sequences have converging running averages \( \rho_n \)? Denote the limit of \( \rho_n \) by \( \rho \). It is then obvious (divide by \( n \)) that these sequences are characterized by

\[
|n \rho - p_n| = o(n) \quad (n \to \pm \infty).
\]

The points \( (n, p_n) \) for sequences with a rotation-number \( \rho \) lie in an ever-widening band around the line \( \rho x \). The width of the band grows slower than \( n \) asymptotically.

---

**Fig. 2.** The dots indicate the pairs \( \phi(n, p_n) \). \( p_{-2} = -1 \) and \( p_{-1} = 0 \) so \( i_{-1} = 1 \); \( p_1 = 2 \) and \( p_2 = 3 \) so \( i_1 = 1 \).
Let \( I(x) \) denote the integer part of \( x \). We define \( \Sigma_\rho \) (not \( \Sigma^*_\rho \)), a subset of the sequences with rotation number \( \rho \), as follows:

\[
p_n = I(n \rho + d),
\]

with the definition of \( i_n \) in terms \( p_n \) as before. In other words

\[
-d \leq n \rho - p_n < 1 - d, \quad d \in [0, 1), \tag{2.1}
\]

or equivalently

\[
0 \leq n \rho + d - p_n < 1, \quad d \in [0, 1). \tag{2.2}
\]

Sequences constructed this way will have rotation-number \( \rho \) (see fig. 3). We will call \( d \) the index.

Another subset \( \Sigma^*_\rho \) of sequences with rotation-number \( \rho \) is defined in a similar way,

\[
-d < n \rho - p_n \leq 1 - d, \quad d \in (0, 1], \tag{2.3}
\]

or

\[
0 \leq n \rho + d - p_n \leq 1, \quad d \in (0, 1]. \tag{2.4}
\]

The integers \( p_n \) for a sequence \( s \) in either \( \Sigma_\rho \) or in \( \Sigma^*_\rho \) are uniquely defined and thus so is the resulting sequence \( s \). If \( \rho \) is given with sufficient accuracy many digits of \( s \) can be easily calculated with a pocket-calculator using criterion (2.1) or (2.3).

\[
\gamma = \rho x + d
\]

Fig. 3. The dots indicate the pairs \((n, p_n)\).
The optimal set $\Sigma_\rho$ (optimal with respect to $\rho$) is defined to be the union of the elements of $\Sigma_\rho$ and of $\Sigma_\rho^*$. It is easy to see that in (2.2) and (2.4) equality is not attained if $d \not\in [\rho]$ (see section 1 for equivalence-classes), because in this case $d + np$ is irrational for all $n$. So for every index $d \in [0, 1]\{\rho\}$ there is a unique sequence $s \in \Sigma_\rho$. If $d \in [\rho]$ equality is attained and there are 2 binary sequences in $\Sigma_\rho$ corresponding to that index, one in $\Sigma_\rho$ and the other in $\Sigma_\rho^*$.

Consider the vertical distances $\eta_n$ in fig. 3 defined by

$$y_n = np + d \quad \text{and} \quad \eta_n = np + d - p_n = y_n \mod 1.$$  \hspace{1cm} (2.5)

So $\eta_n$ is generated by a rigid rotation on the circle $[0, 1)$ with initial condition $\eta_0 = d \in [0, 1)$. The sequences in $\Sigma_\rho$ can also be constructed by partitioning the circle as in fig. 4.

$$i_n = 1, \quad \text{if} \quad \eta_n \in [0, \rho),$$

$$i_n = 0, \quad \text{otherwise}.$$  \hspace{1cm} (2.6)

(This is the construction described by Hockett and Holmes$^4$.) From definition (2.5) of $\eta_n$ it follows that $\eta_n \in [0, \rho)$ is equivalent with $p_n - p_{n-1} = 1$, so that we indeed construct the same sequences. The elements of $\Sigma_\rho^*$ can be gotten by choosing $d$ in $(0, 1)$ and interchanging open and closed endpoints in (2.6). Again for $d \not\in [\rho]$ $\eta_n$ never assumes the values 0 or $\rho$.

The map $s$ from $[0, 1]$ to $\Sigma_\rho$ that assigns to $d$ the sequence belonging to that index is well-defined on $[0, 1]\{\rho\}$. We denote equivalence-classes of sequences with $d$-equivalent indices by $[s_d]$. Then for

$$s: [0, 1]\{\rho\} \to \Sigma_\rho/[s_d]$$

we have

Lemma 2.1. The map $s$ restricted to $[0, 1]\{\rho\}$ is a homeomorphism onto its image.

![Fig. 4. Rotation by $\rho$.](image-url)
Proof. By definition $s$ is well defined and onto. To prove that it is a bijection, let $d$ and $d'$ be two different indices. According to (2.5) we construct two sequences $s$ and $s'$ with

$$\eta_n = \eta_n' + (d' - d) + (p_n - p'_n)$$

(2.7)

and $\eta_n$ and $\eta_n'$ are rotations on the circle (fig. 4). Their orbits are dense and so for some $n$, $\eta_n$ falls in a "1" region while $\eta_n'$ does not. Thus $s$ is a bijection. To prove continuity let $d \in [\rho]$. The numbers $\eta_n$ see (2.5), for $-N \leq n \leq N$ are bounded away from 0 to 1 by a quantity $\delta(N)$ which is decreasing with $N$. For all $d'$ with $|d' - d| < \delta(N)$, we have in the right-hand side of (2.7)

$$\eta_n + (d' - d) \in [0, 1], \quad |n| \leq N.$$

Therefore $p_n = p_n'$ for $|n| \leq N$ and thus

$$d(s, s') < \epsilon = 2^{-N+2}.$$  

In fact for the bijection part we don't have to restrict $s$ to $[0, 1]\setminus[\rho]$. The map establishes a bijection between $[0, 1]$ and $\Sigma_\rho$. This implies that the cardinality of $\Sigma_\rho$ (and of $\Sigma_\rho^+$) is that of the continuum. (The homeomorphism is needed in a later section.)

The following is a statement of the invariance of $\Sigma_\rho$ under the shift.

Lemma 2.2. If $s \in \Sigma_\rho(\Sigma_\rho^+)$ has index $d$ then $s' = \sigma^k s$ is the (unique) element in $\Sigma_\rho(\Sigma_\rho^+)$ with index $d' = (k \rho + d) \mod 1$.

Proof. The sequence $s'$ can be constructed from the same figure as $s$ by translating the origin over the vector $(k, p_k)$. The line $\rho x$ now intersects the new vertical axis at $(k \rho + d) \mod 1$. See fig. 5.  

We now give a formal definition of an optimal sequence and in the main theorem below we prove that elements of $\Sigma_\rho$ satisfy this definition.

Definition. An optimal sequence $s$ (with respect to $\rho$) is a sequence for which

$$\forall k, n \in \mathbb{Z}, \quad |\rho - \rho_n(\sigma^k s)| < \frac{1}{n}.$$  

(2.8)

Note that if $\rho$ is rational, say $p/q$, then $\rho_n(\sigma^k s)$ has to be equal to $p/q$ for all $k$ (this would not be true if we replace $<$ by $\leq$ in 2.8 so that $\rho_n(\sigma^k s)$ could also be

equal to $(j/n)$ for every $n$ co-

$$\frac{m}{n} < \rho$$

For example, consecutive numbers contain either $1/10$ or $5/10$ in the sense that they have at least one digit to the right of the decimal point. All elements of $\Sigma_\rho$ are optimal.

Theorem. $s$

Proof. $\Rightarrow$: Let $s(\sigma^k s)$ Using (2.1)

$$-(k \rho +$$

Since $(k \rho +$ is optimal.
To prove that it is a bijection, we use (2.5) we construct two

\[ \frac{m}{n} < \rho < \frac{m + 1}{n}. \]

Their orbits are dense and so they are not a bijection. Thus \( s \) is a bijection. To

(2.7)

(2.5), for \(-N \leq n \leq N\) are decreasing with \( N \). For

else of (2.7)

Fig. 5. The shift.

equal to \((p \pm 1)/q\). Now suppose that \( \rho \) is irrational and \( s \) is optimal. Then in every \( n \) consecutive digits there are either \( m \) or \( m + 1 \) ones where

\[ \frac{m}{n} < \rho < \frac{m + 1}{n}. \]

For example, if \( \rho \) is the golden mean (=0.6180339887\ldots) then every 3 consecutive digits contain either one or two ones, every 4 consecutive digits contain either two or three ones, and so forth. Optimal sequences provide us with the most regular way to make an irrational average with ones and zeros in the sense that there is a minimal amount of accumulation of identical groups of digits: “1101” is possible but “11011101” is not, because \( \frac{s}{\rho} \) is not close enough to \( \rho \) (also it contains a subsequence with three ones in three digits which is not allowed).

Our main theorem asserts that all optimal sequence are elements of \( \Sigma_\rho \) and all elements of \( \tilde{\Sigma}_\rho \) are onimal sequences (\( \rho \) irrational):

**Theorem.** \( s \in \tilde{\Sigma}_\rho \Leftrightarrow s \) is optimal.

**Proof.** \( \Rightarrow \): Let \( s \in \Sigma_\rho \) so that \( \sigma^s \in \Sigma_\rho \) also. Using (2.1) and using lemma 2.2 we have

\[ -(kp + d) \mod 1 \leq np - np_\rho(\sigma^s) < 1 - (kp + d) \mod 1. \]

Since \((kp + d) \mod 1 \in [0, 1)\), by dividing the above relation by \( n \) we see that \( s \) is optimal.

(2.8)
For \( s \in \Sigma^* \equiv \) and \(< \) change places and now \((k\rho + d) \mod 1 \in (0, 1)\) which also proves that \( s \) optimal.

\( \Leftarrow: \) Suppose \( s \notin \Sigma^* \). According to (2.1) and (2.3) there are then \( l, m \in \mathbb{Z} \) such that for \( s \):

\[
m\rho - p_m = \alpha, \quad \rho - p_l = \beta, \quad \text{and} \quad |\alpha - \beta| \geq 1.
\]

Now let \( p'_n \) count the ones in \( \sigma^n \)s, then:

\[
|(l - m)\rho - p'_{i-1}| = |\alpha - \beta| \geq 1;
\]

so that \( s \) is not optimal.

It can be concluded that the sequences constructed in (2.1) and (2.3) for irrational \( \rho \) have a very balanced distribution of ones and zeros. This observation leads us to expect the orbits corresponding to these sequences in the horseshoe mapping of Hockett and Holmes\(^4\) to have nice properties. If there are any order-preserving-orbits, one would expect these orbits to be candidates.

3. Minimal sets

In this section we prove that \( \Sigma^* \) for each \( \rho \) is a minimal set under the shift operation. The existence of this minimal set was already proven by Hedlund\(^4\), although his approach is slightly different. We attempt to do a more detailed analysis that leads to a picture of \( \Sigma^* \), its elements being interpreted as (pairs of) real numbers. We will prove that \( \Sigma^* \) is a Cantor set. In addition we will give some other examples of minimal Cantor sets. All these results apply to the case that Hockett and Holmes have studied but the results are interesting also in their own right.

The lemma that we want to prove next is most easily understood in the context of fig. 6. For the construction of \( s \) in, say, \( \Sigma^* \), we draw the line \( l: y = \rho x + d \). According to (2.4), when \( l \) crosses a horizontal integer-axis then \( \rho^2 \) increases by one unit. Project the positions \( x_n \) of the crossing of \( y = n \) down to the \( x \)-axis:

\[
x_n = \frac{1 - d}{\rho} + \frac{n}{\rho}.
\]

The convention is that if \( x_n \) for some \( n \) falls in the interval \([l - 1, l)\) then

\[
|(l - m)\rho - p'_{i-1}| = |\alpha - \beta| \geq 1;
\]

so that \( s \) is not optimal.

\[
\begin{align*}
\text{Lemma 3.} \\
\Sigma^* \backslash \{s_p\}.
\end{align*}
\]

Proof. (a) i.

We prove:

So let \( r \notin \) integers \( m \).

\[
|(l - m)\rho - p'_{i-1}| = |\alpha - \beta| \geq 1;
\]

where \( p'_{i-1} \) or (theorem in

\[
|(l - m).
\]
Given the positions $x_n$, one can immediately (by hand) construct the sequence of ones and zeros. (For $s \in \Sigma_p$ redefine: $i_s = 1$ if $x_n \in (l-1, l).$)

**Lemma 3.1.** (a) $\tilde{\Sigma}_p$ is a closed set. In fact (b) $\tilde{\Sigma}_p$ is the closure of $\Sigma_p \setminus \{s_p\} = \Sigma^* \setminus \{s_p\}.$

**Proof.** (a) is proven by showing that $\tilde{\Sigma}_p$ is equal to the set of its contact-points. We prove now that an arbitrary sequence not in $\tilde{\Sigma}_p$ is not a contact-point.

So let $r \not\in \tilde{\Sigma}_p$. Just as in the proof of $\subset$ of the theorem in section 2, there are integers $m, l \in \mathbb{Z}$ such that

$$|(l - m)\rho - p'_{\rho,m}| = |\alpha - \beta| > 1,$$

where $p'_{\rho}$ counts the ones in $\sigma^n r = r'$. However, every sequence $s$ in $\tilde{\Sigma}_p$ obeys (theorem in section 2)

$$|(l - m)\rho - p'_{\rho,m}| < 1,$$

where $p'_{\rho}$ counts the ones in $\sigma^n r = r'$. However, every sequence $s$ in $\tilde{\Sigma}_p$ obeys (theorem in section 2)
$p_i$ counting the ones in $s$. So $r'$ and $s$ have a different number of ones in $l - m$ digits. Then $r$ and $s$ have a different number of ones in $l$ digits.

Or

\[ d(s, r) \geq 2^{-l}, \quad \forall s \in \Sigma_{\rho}, \]

and $r$ is not a contact-point.

To prove (b) we have to show that the sequences with index in $[\rho]$ are contact-points of $\Sigma_{\rho}[s_{\rho}]$.

Let $s \in \Sigma_{\rho}$ have an index $d = -kp \mod 1$, then according to (3.1)

\[ x_n = \frac{k + (kp \mod 1)}{\rho} n + \frac{n}{\rho}. \]

The equation $x_n = l$ with $l$ integer has a solution $l = k$. So one of the $x_n$ falls off a boundary between intervals: $x_n = +k$. (See fig. 7.) Consider a sequence $s' \in \Sigma_{\rho}[s_{\rho}]$ with index $d' = d + \delta$ ($0 < \delta \ll 1$). By definition, the $k$th digits of $s$ and $s'$ are the same; in both cases $x_n$ lands in the $k$th interval $(k - 1, k]$. It can be seen from fig. 7 and proven in the manner in which continuity in lemma 2.1 is proven, that for $\delta \downarrow 0$ the distance $d(s, s')$ is decreasing to zero. (In fact this is the left-continuity.) This proves that there is an $s \in \Sigma_{\rho}[s_{\rho}]$ in every neighborhood of $s$.

This proves the hardest lemma in this section. We now have the following:

**Lemma 3.2.** All orbits in $\Sigma_{\rho}$ are dense in $\Sigma_{\rho}$.

**Proof.** Orbits $\sigma^k$s of an element $s \in \Sigma_{\rho}[s_{\rho}]$ with index $d$ correspond to orbits $(d + kp) \mod 1$ in $[0, 1][\rho]$ according to lemma 2.2. The latter orbits are obviously dense in $[0, 1][\rho]$. Then, because of the two spaces being homeomorphic, the orbit $\sigma^k$s is dense in $\Sigma_{\rho}[s_{\rho}]$. Now, the elements $[s_{\rho}]$ are in the closure of $\Sigma_{\rho}[s_{\rho}]$, so $\sigma^k$s is also dense in all of $\Sigma_{\rho}$.

Consider now the orbit of $r \in [s_{\rho}]$. We just proved that $\sigma^k$s is dense. Then

\[ x_n = k \]

and

\[ x_n = k - \delta \]

\[ 0 1 0 1 1 1 0 1 1 1 0 1 1 0 1 \]

Fig. 7. Upper sequence $s$ with $d \in [\rho]$, lower sequence $s'$ with $d' \in [\rho]$. $s$ and $s'$ are very close.
for every $\varepsilon$ there is an $N$ such that

$$d(\sigma^{-N}s, r) < \frac{\varepsilon}{2^{N+1}}$$

and therefore: $d(s, \sigma^N r) < \varepsilon$ which proves that the orbit of $r$ is dense. \hfill \square

Note that also all forward, $k > 0$, orbits are dense everywhere in $\Sigma_\varphi$, because so are $(d + k\rho) \mod 1$ for $k > 0$ in $[0, 1]$.

This enables us to state our first main theorem of this section:

**Theorem 1.** (Hedlund): $\Sigma_\varphi$ is a minimal set (with respect to $\sigma$).

**Proof.** $\Sigma_\varphi$ is closed and invariant under $\sigma$. Further, every orbit under the shift is everywhere dense, so there is no smaller invariant subset in $\Sigma_\varphi$. \hfill \square

In order to make our proof of the next theorem easier, but also with an eye on applications to be discussed in section 5 we would like to be able to think about sequences as though they were points on the real line. As discussed in the introduction we can identify the space of sequences $S$ with the rectangle $R = [0, 1) \times [0, 2)$ as follows:

$$s \rightarrow (x, y),$$

where

$$s = \cdots i_{-2}i_{-1}i_0 \cdot i_1i_2 \cdots$$

and

$$x = \sum_{i=1}^{\infty} i_i/2^n, \quad y = \sum_{i=0}^{\infty} i_{-i}/2^n.$$ 

The norm on the rectangle is just the induced norm

$$\|(x, y)\| = \sum_{i=0}^{\infty} i_{-i}/2^{n+1} = |x| + |y|$$

and so $R$ (which is now equipped with the Manhattan metric) and $S$ are isomorphic. Interesting questions, of course, are what do $\tilde{\Sigma}_\varphi$ and $\cup_{\varphi \in \mathcal{F}} \tilde{\Sigma}_\varphi$ look like in $R$? However, in later applications we want to work with
semi-infinite sequences and we shall therefore only study the projection of $\Sigma_\rho$ on the $x$-axis (fig. 8): $(x, y) \to (x, 0)$ where $x$ corresponds with a semi-infinite sequence.

Let $\alpha$ denote a real number such that $(\alpha, \beta)$ corresponds to an element $s$ of $\Sigma_\rho$ with index $d$. The ordering of $\Sigma_\rho$ with respect to $d$ is (almost) the same as the ordering with respect to the magnitude of $\alpha$.

**Lemma 3.3.** For elements $s$ in $\Sigma_\rho$: $d > d' \iff \alpha > \alpha'$. Similarly for $\Sigma_\rho^s$.

**Proof.** $\Rightarrow$: Consider two sequences $s$ and $s'$ with indices $d > d'$ (fig. 9). There is a smallest positive integer $k$ such that $x_k$ and $x'_k$ fall in different intervals. According to (3.1) we have $x_k < x'_k$. This implies that $\alpha > \alpha'$.

$\Leftarrow$: The inverse is obtained by noting that $\alpha > \alpha'$ implies $x_k < x'_k$ for some $k$ and thus $d > d'$.

To understand the next lemma, recall from section 2 that there are two different sequences for $d = kp \mod 1$, one in $\Sigma_\rho$ and one in $\Sigma_\rho^s$. We will call these sequences $s$ and $s^*$, corresponding to the real numbers $\alpha$ and $\alpha^*$.

**Lemma 3.4.** Consider the sequences in $\Sigma_\rho$: then (a) $d > d' \iff \alpha > \alpha'$ and $d \neq d'$; (b) Let $d = +kp \mod 1$, there are two sequences with index $d$, $s$ and $s^*$ which differ only in two digits and if $k < 0$ then $\alpha = \alpha^* + 2^k - 1$. If $k > 0$ then $\alpha = \alpha^*$. (See also fig. 8.)

**Proof.** The first statement (a) is equivalent to lemma 3.3. For the proof of (b), note that according to (3.1) the positions $x_n$ (figs. 6 and 7) in the construction of

1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & \\
\hline
\end{array} \]

sequence \( a' \)

sequence \( a \)

\( s \) and \( s^* \) are the same. In both cases, there is an \( n \) such that \( x_n = -k \) and no other \( x_n \) fall on a boundary. In constructing \( s \) and \( s^* \) the only difference is:

\[
\begin{array}{c|c|c}
\hline
i_{-k} & i_{-k+1} \\
\hline
s & 1 & 0 \\
\hline
s^* & 0 & 1 \\
\hline
\end{array}
\]

and all the other digits are the same. In particular

\[
\alpha = \alpha^* + 2^{k+1}, \quad \text{for } k < 0.
\]  (3.2)

For \( k = 0 \), the indices are different, \( d = 0 \) and \( d^* = 1 \) and (a) applies (compare (2.1) and (2.3)). For \( k > 0 \), in projecting down on the real axis the digits that are different are deleted and \( \alpha \) and \( \alpha^* \) are identical.

These lemmas are somewhat subtle. Their consequences, however, are far-reaching. First of all, different elements \( s \) and \( s' \) of \( \Sigma_p \) correspond to different \( \alpha \) and \( \alpha' \) except when \( s \) and \( s' \) both have index \( kp \mod 1 \), \( k > 0 \). Since both sets, \( \Sigma_p \) and its projection, are so closely related we will denote them both (an abuse of notation) by \( \Sigma_p^* \). The statements we make below hold for both sets (unless otherwise mentioned). In other words, \( \Sigma_p^* \) stands for those real numbers in \( [0, 1) \) whose binary expansion yields the right half of a sequence in \( \Sigma_p \). The only sequences that map to the same number are:

\[ s(d) \text{ in } \Sigma_p, \quad s(d) \text{ in } \Sigma_p^* \Rightarrow \alpha(d), \]

where

\[ d = kp \mod 1, \quad \text{for } k > 0. \]  (3.3)

Another consequence of the lemmas is that we can conclude the ordering of \( \alpha \)
is the same as the ordering with respect to $d$, except that at $d = k\rho \mod 1$ $k \leq 1$ there are "gaps" in $\Sigma_\rho$ on the real axis given by (3.2). Note that in (3.2) there are no $\alpha' \in \Sigma_\rho$ such that

$$\alpha < \alpha' < \alpha^*.$$ 

$\alpha$ and $\alpha^*$ have the same index so $\alpha' \in \Sigma_\rho$ is greater than both $\alpha$ and $\alpha^*$ or smaller. Since the gaps occur at all values $d = k\rho \mod 1$, they are dense in $\Sigma_\rho$ and also in the projection of $\Sigma_\rho$.

Notice that the ordering of one orbit in $\Sigma_\rho$ is exactly the same as the ordering of $(d + kp) \mod 1$. That means restricted to $\Sigma_\rho$ the shift is order preserving).

The main conclusion that we want to draw is:

**Theorem 2.** The real numbers in $\Sigma_\rho$ form a Cantor set which is contained in a closed interval of length $\frac{1}{2}$ and not in any smaller interval and which has Lebesgue measure zero.

**Proof.** $\Sigma_\rho$ is closed. The orbits of $x$ under iteration are dense everywhere, so every point is a limit point. The "gaps" are dense, i.e. between every two points in $\Sigma_\rho$ there is a gap. Thus $\Sigma_\rho$ is totally disconnected. The smallest number $\alpha$ in $\Sigma_\rho$ has index 0, the greatest has index 1. Both 0 and 1 are equal to $0 \cdot \rho \mod 1$ and therefore the numbers differ in the first digit only. So, if one has numerical value $\alpha$, then the other has the value $\alpha + \frac{1}{2}$.

The gaps have length $2^{-k-1} k > 1$. Since $\Sigma_\rho^* 1/(2^{k+1}) = \frac{1}{2}$ they form a set of full measure in $[\alpha, \alpha + \frac{1}{2}]$. The remainder has measure zero. ■

Note that when we project $\Sigma_\rho$ on the y-axis, none of the reasoning changes except that we have one digit (the zeroth) more to worry about. This projection would yield a Cantor set contained in an interval of length one.

As we have said before, these results carry over to the study of the dynamics on a horseshoe (shift on bi-infinite sequences). In Hockett and Holmes the horseshoe for a time 1 map of a particular flow is constructed. The domain of the time 1 map is an annulus. It is proven there that the orbits of this map, corresponding to orbits in $\Sigma_\rho$, can be assigned rotation numbers in the way we defined them. $\Sigma_\rho$ corresponds to a minimal Cantor set in the horseshoe. Under certain additional conditions orbits in $\Sigma_\rho$ are indeed order-preserving. We shall show below that there are in fact uncountably many minimal Cantor sets for each irrational $\rho$. These other sets are not optimal.

Let $\rho$ be a fixed irrational number. We will now construct a continuum of minimal Cantor sets $\Sigma_\rho(e)^*$. They will be continuously parametrized by the parameter $e$ and have rotation number $\rho$. The construction is as in fig. 10. We draw two line rotation-points $\alpha$ to the coordinates of these points...
Note that at $d = k\rho \mod 1 \leq 1$ for all $k$. Note that in (3.2) there is a typo: the correct ordering is $0$.

Both $\alpha$ and $\beta$ are dense in $\overline{\Sigma}_\rho$, which is contained in a digit interval and which has

\[ e \in [1, 1/\rho]. \]

For $e = 1/\rho$ we have the optimal set $\overline{\Sigma}_\rho$ back. For $e$ and $\rho$ fixed and $d$ varying in $[0, 2]$, one proves by an analysis similar to the one in this section and the two lemmas in section 2, that $\overline{\Sigma}_\rho(e)$ is also a minimal Cantor-set (for each $e$). More complicated sets, parametrized by $n$ parameters $e_1, \ldots, e_n$, can be constructed by drawing $n + 1$ lines each with points on it separated distance $(n + 1)/\rho$.

The last example of a minimal Cantor set is constructed in a way very similar to the construction of the optimal set in section 2. Instead of a straight line $y = px + d$, we draw a periodically oscillating line (see fig. 11). Let $g(x)$ be a function with period 2 and

\[ |g'(x)| < 1. \]

Eqs. (2.2) and (2.4) are replaced by

\[ S_\rho: \quad 0 \leq np + d + g(np + d) - p_n < 1, \quad d \in [0, 1], \]

\[ S_\rho^*: \quad 0 < np + d + g(np + d) - p_n \leq 1, \quad d \in (0, 1]. \]

![Fig. 10. A sequence belonging to $\overline{\Sigma}_\rho(e)$](image)
Note that if $g(x)$ has period 1 then $g(xp)$ has period $1/\rho$. Similar to (2.5) we define $y_n$ to be

$$y_n = np + d + g(np + d).$$

Again the same analysis as before will show that the union of $S_\rho$ and $S_\rho^*$ is a minimal Cantor set. We mention this example specifically because it plays an important role in the study of ground state configurations in the Frenkel-Kontorova model\(^5\). In fact, (3.4) has exactly the same form as the expression for ground state configurations with rotation-number $\rho$ in the work of Aubry and Le Daeron (except that in their work $g$ can possibly have countably many jumps per period).

Finally we mention without proof that if $\rho = p/q$ where $p$ and $q$ relative prime then the set $\bar{S}_\rho$ is finite. It actually consists solely of one sequence and its iterates of which there are $q$, since the sequence is $q$-periodic. For example:

$$\bar{S}_{1/3} = \{(100)^*, (010)^*, (001)^*\}.$$

4. Continued fractions

In this section we consider again the optimal sequences as defined in section 3. We will restrict ourselves to semi-infinite sequences. First we will (for any sequence optimal to $\rho$) consider the sequence of numbers $(p_n/n)^*$ and prove that the continued fraction expansion of the number $\rho$ is a subsequence of

\[ q_{i+1} = \frac{q_i}{Q_i}, \]

so that

\[ \frac{q_i}{Q_i} = \rho = \frac{l_i}{n_i} \]

or

\[ \rho = \left[ l_i \right] \]

\[ |Q_n\rho| \]

According
these numbers. On the other hand we can also construct a semi-infinite
sequence from the knowledge of the continued fraction expansion of $\rho$. The
construction of this sequence is symbolic; it involves no calculations, only
symbolic manipulations of ones and zeros. This sequence is then shown to be a
member of $\overline{S}_p$.

The continued fraction expansion $\{q_n/Q_n\}_0^\infty$ with continued fraction
coefficients $\{\alpha_i\}_1^\infty$ of the number $\rho$ is defined as follows:

$$q_{i+1} = \alpha_{i+1}q_i + q_{i-1}, \text{ with } q_0 = 0, \ q_1 = 1,$$
$$Q_{i+1} = \alpha_{i+1}Q_i + Q_{i-1}, \text{ with } Q_0 = 1, \ Q_1 = \alpha_1; \quad (4.1)$$

so that

$$q_i = \frac{1}{Q_i} \frac{1}{\alpha_i + \cdots \frac{1}{\alpha_1}},$$

and

$$\rho = \lim_{n \to \infty} \frac{q_n}{Q_n},$$
or

$$\rho = [\alpha_1, \alpha_2, \alpha_3, \ldots].$$

**Proposition.** Let $s \in \overline{S}_p$ have an index $d \in [0, 1]$. Then there is an $N > 0$ such
that $\{q_n/Q_n\}_N^\infty$ is a subsequence of the running averages $\{\rho_n(s)\}_1^\infty = \{p_n/n\}_1^\infty$.

**Proof.** The continued fractions $q_n/Q_n$ have the following basic property.

The numbers $q_n$ and $Q_n$ are those numbers for which

$$|Q_n\rho - q_n| < |Qp - q|, \ \forall q, Q \in \mathbb{N} | Q < Q_n \quad (4.2)$$

and

$$|Q_n\rho - q_n| < 1/Q_n.$$

According to the definition of $p_n$ in (2.1) and (2.3) (figs. 2 and 3), if we choose $N$
so that

\[ Q_N > 1/d \quad \text{and} \quad Q_N > 1/(1 - d) \]

\[ \{q_n/Q_n\}_n \] will be a subsequence of \( \{p_n/n\}_1 \).

\[ \rho = \]

Note that (4.2) provides us with an excellent and fast criterion for finding \( q_n/Q_n \) numerically while constructing \( s \). From that one can deduce the coefficients \( \alpha \).

Consider a sequence \( s \) with index \( d \) and shift this sequence \( Q_n \) places. The new sequence \( s' = \sigma^Q s \) has index

\[ d' = (d + Q_n \rho) \mod 1 = d + Q_n \rho - q_n, \]

which is closer to \( d \) than the index of any other \( \sigma^Q s \) with \( Q < Q_n \). The sequence \( s' \) could therefore be very close to \( s \) and start out with many digits the same as in \( s \). The greater \( Q_n \), the more digits might be identical. This insight leads us to construct a semi-infinite sequence by repeating larger and larger pieces and putting them together in one sequence. The sequence resulting from the following construction will be called the scaling sequence.

First we define some operations in order to be able to do symbolic manipulation with sequences. Define "·" as repeating and "⊕" as concatenation. So:

\[ 3 \cdot 010 \oplus 111 = 010010010111. \]

Note that we can multiply a sequence only by a positive integer and that the operations are not commutative. The truncation \( t_n(s) \) is the subsequence of \( s \) consisting of its first \( N \) digits.

**Example.** \( t_3(3 \cdot 010 \oplus 111) = .0100 \)

The construction of the scaling sequence draws on a complete analogy with the definition of continued fractions in (4.1), where now \( q_i \) stands for the number of ones in the first \( Q_i \) digits. The zeroth digit, or \( t_{Q_0} s \) (left of the binary point), is defined to be "0" (step 0). The construction of step 1 is: write down a subsequence of length \( \alpha_1 (= Q_1) \) with one (= \( q_1 \)) "1". If \( \alpha_1 > 1 \) there is more than one possibility of doing this. The convention ("initial condition") is that the "1" always comes as the last (\( \alpha_1 \)st) digit. We have constructed the first \( Q_1 \) digits of \( s \) or \( t_{Q_1} s \). The other steps are given by (compare with (4.1))

\[ t_{Q_{n+1}} s = \alpha_{n+1} \cdot t_{Q_n} s \oplus t_{Q_{n-1}} s. \quad (4.3) \]

We give and \( Q_n \)

\[ \rho = \]

\[ \rho = \]

We give three examples; the bars indicate the digit $Q_n$ with the numbers $q_n$ and $Q_n$ written above resp. below it:

\[
\rho = [1, 1, 1, \ldots]; \quad 0 \cdot 1|0|1|10|101|10110\ldots; \\
\begin{array}{cccccc}
1 & 2 & 3 & 5 & 8 & 13 \\
1 & 2 & 3 & 5 & 8 & 13
\end{array}
\]

\[
\rho = [2, 1, 2, 1, 2, 1, \ldots]; \quad 0 \cdot 01|0|01001|010|0100100101001001001 \ldots; \\
\begin{array}{cccccc}
1 & 1 & 3 & 4 & 11 \\
2 & 3 & 8 & 11 & 30
\end{array}
\]

\[
\rho = [5]; \quad 0 \cdot 00001|00001|00001 \ldots; \\
\begin{array}{cccc}
1 & 2 & 3 \\
5 & 10 & 15
\end{array}
\]

Note that if $\rho$ is rational, there is a finite number of coefficients but to obtain the sequence we keep repeating to finally get a periodic sequence.

The main theorem of this section is:

**Theorem.** The scaling sequence belongs to $\Sigma_\rho$, in fact, they have index $\rho$.

The proof is a generalization of the integer decomposition as described by Kadanoff\(^7\). The reader may profit from checking the statements in the proof against the examples of scaling sequences given above.

**Proof.** We will consider the $k$-truncation $t_k s$ of the scaling sequence $s$ and prove that the number of ones $p_k$ in $t_k s$ satisfies relation (2.1) with $\alpha$ equal to $\rho$. In order to be able to do this for every $k \in \mathbb{N}$ we have to "decompose" $t_k s$ into terms like $t_{Q_n} s$. First decompose $t_k s$ as follows:

\[
t_k s = \bigoplus_{i=0}^{n-1} t_{Q_{n-i}} \circ s \bigoplus \text{"rest"},
\]

where $Q_n$ is the greatest continued fraction denominator smaller than or equal to $k$. By construction $\delta_n \leq \alpha_{n+1}$. Then repeat this step for "rest", and so on:

\[
t_k s = \bigoplus_{i=0}^{n-1} \delta_{n-i} \cdot t_{Q_{n-i}} \bigoplus t_{\text{rest}},
\]

where $\delta_{n-i} \leq \alpha_{n-i+1}$ and $r < \alpha_1$ and if $\delta_{n-i} = \alpha_{n-i+1}$ then $\delta_{n-i-1} = 0$ (Recall that $\alpha_{n-i+1} \cdot t_{Q_{n-i}} s \bigoplus t_{Q_{n-i+1}} s = t_{Q_{n-i+1}} s$). We can now evaluate $kp - p_k$ as follows:

\[
kp - p_k = \sum_{i=0}^{n-1} \delta_{n-i} (\rho Q_{n-i} - q_{n-i}) + (\rho r - p_k).
\]
The problem reduces to finding an upper- and lower-bound for this last expression. In the rest-term \( r < \alpha_1 \) and therefore \( p_r = 0 \) (number of ones). The smallest value of \( pt - p_r \) is 0 and its greatest value is \( \rho(\alpha_1 - 1) \).

Recall the property of continued fraction\(^{9,40}\) that for \( n - i \) odd \( \rho Q_{n-i} - q_{n-i} \) is greater than zero and for \( n - i \) even it is smaller than zero. For \( k < O_{2n+1} \) we can calculate the maximum of \( \rho k - p_k \) by simply adding up all the possible positive contributions and likewise we calculate the minimum:

\[
\min_{k < O_{2n+1}} \{ \rho k - p_k \} = \sum_{i=1}^{n} \alpha_{2i-1} (\rho Q_{2i-1} - q_{2i-1}) + (\alpha_1 - 1) \rho,
\]

\[
\max_{k < O_{2n+1}} \{ \rho k - p_k \} = \sum_{i=1}^{n} \alpha_{2i} (\rho Q_{2i} - q_{2i}) + 0.
\]

Using definition (4.1) we can rewrite these expressions; for instance:

\[
\sum_{i=1}^{n} \alpha_{2i} q_{2i-1} = \sum_{i=1}^{n} q_{2i} - q_{2i-2} = q_{2n}.
\]

This yields:

\[
\min_{k < O_{2n+1}} \{ \rho k - p_k \} = \rho (Q_{2n+1} - 1) - (q_{2n+1} - 1),
\]

\[
\max_{k < O_{2n+1}} \{ \rho k - p_k \} = \rho (Q_{2n} - 1) - q_{2n}.
\]

This tells us that the minimum occurs at digit \( Q_{2n+1} - 1 \) and the maximum at digit \( Q_{2n} - 1 \). Taking the limit for \( n \to \infty \) and noting that all contributions have the same sign, we find

\[-\rho < \rho k - p_k < 1 - \rho.\]

Thus the scaling sequence satisfies (2.1) with index \( \rho \). (Note that inequality is not attained here because we consider only \( k > 0 \).)

The question now arises how we can change the first steps of the construction of the scaling sequence and still end up in \( \Sigma_\rho \). Suppose first that \( \alpha_1 \) is greater than 1. The first step in assembling the scaling sequence is to place the "1" at digit number \( \alpha_1 \). Suppose we put it at digit number \( \alpha_1 - 1 \). In carrying out the recursive recipe (4.3) to piece the whole sequence together, it is clear that every "1" now moves ahead precisely one digit. This means that we have built \( \sigma \alpha \), the

shifte

Proof.
shifted scaling sequence (compare with our second example!). One can continue shifting like this until the “1” is at digit number one. For further shifting if “1” is at digit number one, remove the first bar, permute the first $Q_2$ digits cyclically (one step) to the left and then pick up the construction as in (4.3). One can see this by explicitly doing this for the examples given!

It should be obvious that if we change the total number of “1’s” at any step of the construction the resulting sequence is certainly not in $\bar{\Sigma}_\rho$. (By adding one “1” for instance, we would obtain $(q_n + 1)/Q_\rho$ as continued fractions of $\rho$.)

To find analogous recursive relations for sequences in $\bar{\Sigma}_\rho$ with $d \notin [\rho]$ seems a harder problem, although, of course, we can approximate every sequence in $\bar{\Sigma}_\rho$ arbitrarily well by the shifts of the scaling sequence.

In the last part of this section we prove that the scaling sequence for quadratic irrational numbers $\rho$ is an attracting fixed point of a very simple linear operator $T$ defined on the space of semi-infinite sequences.

Consider the subset of quadratic irrational rotation-numbers $\rho$ with $\rho = [(a_1 \ldots a_n)]$. (All quadratic irrationals have continued fraction coefficients which are eventually periodic.) The construction of the scaling sequence with such a rotation number is $k$-periodic; after performing $k$ steps with (4.3) we have the same coefficients for the construction. If one could perform $k$ steps at one time the coefficients of the construction would again be constant. One would construct $t_{Q_\rho} s, t_{Q_\rho} s, \ldots, t_{Q_\rho} s, \ldots$ etc. An interesting way of doing this is described in Feigenbaum and Hasslacher).

To construct the scaling sequence $s$ define a linear operator $T$ so that:

$T: t_{Q_\rho} s \rightarrow t_{Q_\rho} s$.

**Proposition.** If $T$ satisfies the above equation for the scaling sequence $s$ with $\rho$ quadratic irrational, then for all $n > 0$:

$T: t_{Q_{n+1}} s \rightarrow t_{Q_{n+1}} s$.

This proposition tells us that if $T$ constructs $t_{Q_\rho} s$ from $t_{Q_\rho} s$ then we can construct $t_{Q_\rho} s$ and on. For $\rho = [2, 1, 2, 1, \ldots]$ as in the second example we write down $T$:

$T$

| 0 → 010 |
| 1 → 01001 |

In the proof we will assume $k$ to be 2 for simplicity. This proof can be generalized easily to $k > 2$.

**Proof.** By induction. Suppose that the proposition holds for $n = 1, 2, 3, \ldots, N$,
then for \( n = N + 1 \) we have by applying (4.3) twice and relying on the linearity of \( T \):

\[
T(t_{O_{2N+2}}) = T[\alpha_{2N+2} \cdot (\alpha_{2N+1} \cdot t_{O_{2N}} + t_{O_{2N-1}}) + t_{O_{2N}}]
= \alpha_{2N+2} \cdot [\alpha_{2N+1} \cdot T(t_{O_{2N}}) + T(t_{O_{2N-1}})] + T(t_{O_{2N}})
= \alpha_{2N+2} \cdot (\alpha_{2N+1} \cdot t_{O_{2N+2}} + t_{O_{2N+1}}) + t_{O_{2N+2}}.
\]

And by the 2-periodicity of \( \alpha_n \), this expression equals \( t_{O_{2N+2}} \). The proposition then holds for \( n = N + 1 \) as well. By definition of \( T \), the proposition holds for \( n = 1 \).

**Remark.** The fact the sequence constructed in this fashion is invariant under the inverse of \( T \) which decreases the number of digits, makes these sequences apt for the decimation procedure for path integrals\(^5\).

5. The piecewise linear circle map

The fact that \( \bar{\Sigma}_p \) is invariant under the shift means that the real numbers \( \alpha \) associated with the one-sided version of \( \bar{\Sigma}_p \) (see section 3) are invariant under

\[
\theta : \alpha \rightarrow 2\alpha \mod 1.
\]

Recall that to the semi-infinite sequences \( s = \{O_n\}_{n=-1}^{\infty} \) in \( \bar{\Sigma}_p \) we assign real numbers as follows:

\[
\alpha = \sum_{n=1}^{\infty} \frac{i_n}{2^n}, \quad \rho = \lim_{N \to \infty} \frac{1}{N} \sum_{n=1}^{N} i_n.
\]

The set of numbers \( x \) corresponding to \( s \) in \( \bar{\Sigma}_p \) is also called \( \bar{\Sigma}_p \) and \( \rho \) assumes one value only, the rotation number associated with \( \bar{\Sigma}_p \). The results for optimal sequences will lead us to construct a modification \( \phi_\beta \) of \( \theta \). For the family \( \phi_\beta \) (piecewise linear) we shall calculate exactly the width of the \( p/q \) resonance interval. (A \( p/q \)-resonance interval is the interval of values for \( \alpha \) such that \( \phi_\alpha \) has a stable \( q \)-periodic orbit with rotation-number \( p/q \).) In the last part of this section we generalize our result to a slightly wider class of piecewise linear circle-maps.

In section 3 we found that the real numbers \( \alpha \in \bar{\Sigma}_p \) form a Cantor set contained in \([\alpha_p/2, \alpha_p + 1/2]\), for some \( \alpha_p \), and in no smaller interval. This observation leads to the following construction, similar in spirit to the construc-
For every $\beta \phi_\beta$ is a continuous degree one critical circle map. If $\beta = \alpha$ then restricted to $\tilde{\Sigma}_\rho$ the map $\phi_{\alpha}$ is the map $2x \mod 1$. The invariant set $\tilde{\Sigma}_\rho$ can then be constructed on the circle by taking out $((\alpha + 1)/2, \alpha/2)$ and all its inverse iterates under $\phi_{\alpha}$ (see fig. 13). Note that $\alpha/2$ and $(\alpha + 1)/2$ correspond to sequences with index 0 and 1 resp. and the difference between their inverse images correspond exactly to the "gaps" in the Cantor set form lemma 3.4 and theorem 2 in section 3.

We are going to study the rotation-number of $\phi_\beta$ as a function of $\beta$. The rotation-number is defined in terms of the lift $\phi_\beta$ of $\phi_\beta$:

$$\text{rotation-number} = \lim_{n \to \infty} \frac{\Phi_\beta^n(x) - x}{n}.$$
Lemma 5.1. Let $\alpha$ correspond to $s \in \Sigma_\rho$ and $i_j$ the digits of the binary expansion of $\alpha$. Then
\[
\lim_{n \to \infty} \frac{\Phi_{a_\rho}(\alpha) - \alpha}{n} = \lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} i_j.
\]

Proof. Restricted to $\Sigma_\rho$, $\Phi_{a_\rho}$ is just the shift. The integer part of $\Phi_{a_\rho}(\alpha)$ increases by one if $\alpha \mod 1 \geq \frac{1}{2}$, in other words if the first digit is a one. \]

To proceed we quote some important results for circle-maps. These statements and their proofs can be found in Boyland\textsuperscript{8}) or Newhouse, Palis, Takens\textsuperscript{11}) and Ito\textsuperscript{12}). Let $\text{End}(S^1)$ be the set of all continuous degree one circle maps with $C^0$-topology. Let $h$ and $g$ be maps in $\text{End}(S^1)$ such that their lifts $H$ and $G$ are non-decreasing. The following results then hold:

Lemma 5.2. Every map $f \in \text{End}(S^1)$ has a closed rotation-interval $[\rho(f), \rho(f)]$, i.e.: for every $\rho$ in this interval there is an orbit of $f$ with rotation number $\rho$ and no orbit has rotation-number not in this interval.

Lemma 5.3. The map $\rho$ that assigns to $f$ the endpoints of its rotation-interval:
\[
\rho: \text{End}(S^1) \to \mathbb{R}^2
\]

is continuous.

Lemma 5.4. $\rho(h) = \lim_{n \to \infty} (H^n(x) - x)/n$ exists and is independent of $x$. ($h$ has a single well-defined rotation-number.)

Lemma 5.5. Let $G(x) < H(x)$ for all $x$. Then if $\rho(g)$ or $\rho(h)$ irrational $\rho(g) < \rho(h)$. If $\rho(g)$ and $\rho(h)$ are rational, equality is allowed: $\rho(g) \leq \rho(h)$. 

---

*Fig. 13. 3 steps in the construction of the Cantor-set $\Sigma_\rho$ by inverse images.*
Lemma 5.6. If $\rho(g) = p/q$, a rational number $\leftrightarrow g$ has a $p/q$ periodic orbit.

From all this it follows that there is a well-defined continuous mapping that assigns to $\phi_\beta$ a single rotation-number. The $\phi_\beta$ form a one-parameter family of mappings for which the topology carries nicely over to the parameter space $\beta \in [0, 1]$: $\beta_1$ and $\beta_2$ are close if and only if $\phi_{\beta_1}$ and $\phi_{\beta_2}$ are $C^6$-close. So we define a continuous mapping $R$ that assigns to $\beta$ the rotation number of $\phi_\beta$.

$$R: \beta \to \rho(\phi_\beta).$$

According to lemma 5.5 $R$ is non-decreasing and strictly increasing on those values of $\beta$ where $\rho(\phi_\beta)$ is irrational. It follows that $R$ may have plateaus where $\rho(\phi_\beta)$ is rational, say $p/q$ and where (lemma 5.6) $\phi_\beta$ has a $p/q$ periodic orbit. The parameter values for which we find these $p/q$ plateaus are denoted by $I_{p/q}$ ($p/q$-resonance intervals).

The idea of the construction is that to some extent we already know what the map $R$ is (namely on the points where it assumes irrational values).

Lemma 5.7. Let $\alpha_p = 2$ be the element in $\Sigma_p$ with index $d = 0$, then $\phi_{\alpha_p}$ has rotation number $\rho$ ($\rho$ irrational).

Proof. $\phi_{\alpha_p}$ restricted to $[\alpha_p/2, (\alpha_p + 1)/2]$ in just $2x \mod 1$. There is an invariant set $\Sigma_p$ in $[\alpha_p/2, (\alpha_p + 1)/2]$ and orbits in that set have rotation-number $\rho$. Therefore (lemma 5.4) all orbits have rotation-number $\rho$.

On the other hand we can construct $\alpha_p$: since it has index $\rho$ (because $\alpha_p/2$ has index zero and lemma 2.2), its binary sequence is just the scaling sequence defined in section 4. In addition we know that $R$ is strictly increasing at $\alpha_p$ (lemma 5.5). We thus know the map $R$ for all values of $\beta$ where $R(\beta)$ is irrational.

Lemma 5.8. The set $I$ of values $\beta$ for which $R(\beta) = \rho(\phi_\beta)$ is irrational, has zero (Lebesgue) measure.

Proof. $I$ consists of the numbers $\alpha_p$ for $\rho$ irrational and $\alpha_p$ corresponds to the scaling sequence in $\Sigma_p$. Therefore $I$ is a subset of $\cup_{\rho \text{irr}} \Sigma_p$ on the real line. For each irrational $\rho$, $\theta$ (see beginning of section) maps the set of real numbers $\Sigma_p$ to itself and is a bijection restricted to $\Sigma_p$ (in $\Sigma_p$ sequences with indices 0 and 1 get mapped to the sequence with index $\rho$). So $\theta$ restricted to $\cup_{\rho \text{irr}} \Sigma_p$ is a bijection. But $\theta$ is expanding (derivative 2) so $\mu(\cup_{\rho \text{irr}} \Sigma_p) > \mu(\theta(\cup_{\rho \text{irr}} \Sigma_p)) \in [0, 1]$. No number whose binary expansion begins with .0011 or with .1100 can
be an element of $\bigcup_{\rho \in \mathcal{R}} \Sigma_{\rho}$ (compare eq. 2.8)). So we also have:

$$\mu \left( \bigcup_{\rho \in \mathcal{R}} \Sigma_{\rho} \right) \leq \frac{\gamma}{\delta}.$$ 

Therefore $\mu(I) \leq \mu \left( \bigcup_{\rho \in \mathcal{R}} \Sigma_{\rho} \right) = 0$. \hfill \blacksquare

Note that in the same way we can prove that $\bigcup_{\rho \in \mathcal{R}} \Sigma^*_{\rho}$ has measure zero and therefore $\bigcup_{\rho \in \mathcal{R}} \Sigma_{\rho}$ has measure zero. It follows from this lemma that the complement of $I$ (or the union of all $I_{p/q}$) has measure 1.

We can think of the interval $I_{p/q}$ as being squeezed in between values $\alpha_{p/q}$ where $R(\alpha_{p/q})$ is irrational (see fig. 14). Because $R(\beta)$ is continuous and increasing we can find the length of $I_{p/q}$ by

$$I_{p/q} \subset [\alpha_{p-}, \alpha_{p+}],$$

$$p_\varepsilon = \frac{p}{q} \pm \varepsilon \quad (\varepsilon \text{ irrational}).$$

and taking the limit $\varepsilon \to 0$. The sequences $\alpha^*_\rho$ can be easily constructed (being scaling sequences). In this manner we prove:

**Theorem 1.** The length of $I_{p/q}$ is $1/(2^q - 1)$. The reader may profit from comparing the statements in the proof with the table below.

**Proof.** Let $p_\varepsilon = p/q \pm \varepsilon$ with $\varepsilon$ irrational. For small enough $\varepsilon$, $p_\varepsilon$ will be very well approximated by $p/q$ and so $p/q$ will be a continued fraction of $p_\varepsilon$. In fact let $p/q = [\alpha_1, \ldots, \alpha_k]$, the $\alpha_i$ are not unique, then $\varepsilon \to 0$ implies $\alpha_{k+1} \to \infty$.

![Fig. 14. The map R (a Cantor-function).](image-url)
Knowing the coefficients we can now construct the sequences \( \alpha_{p^\pm} \). Both will have \( p \) ones in the first \( q \) digits. This group of \( q \) digits will then be repeated \( \alpha_{k+1} \) times (see (4.3)) in the next step of the construction:

\[
\alpha_{p^\mp} = \underbrace{p}_{1} \underbrace{q}_{\ldots} \underbrace{2}_{\ldots} \underbrace{a_{k+1}}_{\ldots} \ldots,
\]

Obviously, for \( \varepsilon \to 0 \), \( \alpha_{p^\pm} \) will be a periodic sequence as its limit. The rotation-number in the limit sequence will be \( p/q \). The difference between \( \alpha_{p^+} \) and \( \alpha_{p^-} \) depends only on the first \( q \) digits.

To construct \( \alpha_{p^+} \) and \( \alpha_{p^-} \) let \( 0 < n < q \). At digit \( q - n \) we have \( p_{q-n} \) ones where \( p_{q-n} \) satisfies (2.2):

\[
0 \leq (q - n)p - p_{q-n} + d < 1
\]

and

\[
d = \rho = \frac{p}{q} \pm \varepsilon,
\]

so

\[
0 \leq p + \frac{1 - np}{q} - p_{q-n} \pm \varepsilon(q - n + 1) < 1.
\]

In this last equation \((1 - n)p/q \) is fractional for \( n \neq 1 \). So, for \( n \neq 1 \) and \( \varepsilon \) small enough, \( p_{q-n} \) does not depend on the sign of the \( \varepsilon \)-term. However, for \( n = 1 \) it does. For the digits \( i_{q-1} = p_{q-1} - p_{q-2} \) and \( i_1 = p_{q} - p_{q-1} \) we have:

\[
\alpha_{p^+}: \quad i_{q-1} = 0, \quad i_q = 1,
\]

\[
\alpha_{p^-}: \quad i_{q-1} = 1, \quad i_q = 0.
\]

We take the limit as \( \varepsilon \to 0 \) and the sequences become periodic and

\[
\alpha_{p^+} = \alpha_{p^-} + 2^{-q} + 2^{-2q} + \cdots = \alpha_{p^-} + 1/(2^q - 1).
\]

Thus \( I_{pq} = [\alpha_{p^-} + 1/(2^q - 1)] \).

We note that this proves the relation

\[
\sum_{(p,q) \in U} \frac{1}{2^q - 1} = 1.
\]
where \( U \) is the set of pairs \((p, q)\) such that \( p \) and \( q \) are relative prime, \( p < q \) and \( q \geq 2 \). Note that \( \alpha_{p+} \) can be calculated easily using the fact that \( \alpha_{p+} \) is the scaling sequence for \( \rho = p/q \).

Table I which we give below was made as follows. For a given \( \rho \) we calculated the scaling sequence by (2.2), setting \( d = \rho \). The bars that indicate continued fraction denominators were found numerically by criterion (4.2). The continued fraction coefficient can then easily be deduced through (4.1). One can check that the resonance intervals have length \( \alpha_+ - \alpha_- = \frac{1}{39} \).

Consider again the space of sequences \( S \). To generalize the foregoing we

Note that the numbers under the ordering to the interval that the parameters differ only in similar coefficients. We can parameterize the cut-off point. It can be seen that has a fixed point:

\[ \beta \in \]

We expect the specific.

Let \( \alpha \in \rho = 1/n \).

As before restricted of the orb:
regard them now as numbers on the base $\tau$ where $\tau > 1$. As in section 3 we associate numbers $x$ and $y$ with each sequence as follows:

$$s = \cdots i_{-2}i_{-1}i_0 \cdot i_1 i_2 \cdots,$$

$$\bar{x} = \sum_{1}^{\infty} i_n/\tau^n, \quad \bar{y} = \sum_{0}^{\infty} i_n/\tau^n,$$

but now

$$x = \bar{x} \mod 1, \quad y = \bar{y} \mod \tau.$$

Note that this mapping from $S$ to the rectangle $R$ a bijection only for $\tau = 2$. It is onto for $1 < \tau \leq 2$ and it is one-to-one for $\tau \geq 2$.

The set of optimal sequences $\mathcal{S}_\rho$ is invariant under the shift. The set of numbers $\bar{a} \in \mathcal{S}_\rho$ corresponding to one-sided sequences in $\mathcal{S}_\rho$ is now invariant under multiplication by $\tau$ and so is the set $\{a\} = \{\bar{a} \mod 1\}$. Furthermore the ordering of the projections $\bar{a}$ is (almost) the same as the ordering with respect to the index: lemmas 3.3 and 3.4 still hold if $\alpha$ is replaced by $\bar{a}$. This implies that the smallest number $\bar{a}$ in $\mathcal{S}_\rho$ has index 0 and the biggest has index 1. They differ only in the first digit, i.e.: their difference is $1/\tau$. This enables us to do a similar construction as before.

We construct a degree one continuous circle map which now has two parameters $\tau$ and $\beta$: $\Phi_{\tau, \beta}$. The construction is similar to the previous one, $\beta$ is a cut-off parameter, $\tau$ is the slope of the slanted part of the map (figs. 15 and 16). It can be seen from the figure that for $\beta = 0$ and for $\beta = 1/(\tau - 1)$ the map $\Phi_{\tau, \beta}$ has a fixed point. The parameter range of $\beta$ that we are interested in is

$$\beta \in \left[0, \frac{1}{\tau - 1}\right].$$

We expect the map $\Phi_{\tau, \beta}$ to attain all rotation-numbers in $(0, 1)$ for some $\beta$ in the specified interval.

Let $\alpha \in \mathcal{S}_\rho$ have digits $i_n$ and

$$\rho = \lim_{n \to \infty} \frac{1}{n} \sum_{1}^{n} i_n.$$

As before, if $\beta$ has the value $\alpha_\rho$ where $\alpha_\rho$ is constructed with index $d = \rho$, then restricted to $\mathcal{S}_\rho$, the map $\Phi_{\tau, \alpha_\rho}$ is just multiplication by $\tau$. The rotation-number of the orbits of the invariant set $\mathcal{S}_\rho$ is the average number of ones, $\rho$. Therefore we
can associate the rotation-number $\rho$ with (every orbit of) the mapping $\phi_{r,\alpha_r}$.
(Note that $\alpha_r$ depends on $r$.)

Let $r > 1$. Theorem 1 generalizes to

*Theorem 2.* The resonance interval $I_{p/q}$ of the family $\phi_{r,\beta}$, $r$ fixed, has length $(r - 1)/(r^q - 1)$. The union of all $I_{p/q}$ has full measure.

*Proof.* The $p/q$ resonance intervals are constructed exactly as before. The particular we have that in the binary expansions of $\alpha_{p-1}$ and $\alpha_{p+1}$, the digits $i_{p-1}$ and $i_{p+1}$ interchange (in the limit $\epsilon \to 0$ see proof of theorem 1).

---

![Graph](image_url)

**Fig. 15.** Construction of the truncated map $\phi_{r,\beta}$ for $r = 1\frac{1}{2}$. Fixed point when $\beta = 0$ or $\beta = 2 \neq 1/(1\frac{1}{2} - 1)$.

![Graph](image_url)

**Fig. 16.** Construction of $\phi_{r,\beta}$ for $r = 4$. Fixed point when $\beta = 0$ or $\beta = 1/3 = 1/(4 - 1)$.
Therefore
\[
\alpha_{p,r} = \alpha_{p_-} + (\tau^{-q+1} - \tau^{-q}) + (\tau^{-2q+1} - \tau^{-2q}) + \cdots
\]
\[
= \alpha_{p_-} + (\tau - 1)(\tau^{-q} + \tau^{-2q} + \cdots)
\]
\[
= \alpha_{p_-} + \frac{\tau - 1}{\tau^q - 1}.
\]

To prove the union of $I_{p,q}$ has the full measure we can try and prove that the complement $I$ of $\bigcup I_{p,q}$ has zero measure. For $\tau \geq 2$ the proof of lemma 5.8 applies. However, for all $\tau > 1$, we can also prove directly the equality:
\[
\sum_{(p,q) \in U} \frac{\tau - 1}{\tau^q - 1} = \frac{1}{\tau - 1},
\]
where $U$ is the set of pairs $(p, q)$ such that $p$ and $q$ are relative prime, $p < q$ and $q \geq 2$. By definition of Euler's $\phi$ function this can be written as
\[
\sum_{q \geq 2} \phi(q) \frac{\tau - 1}{\tau^q - 1} = \frac{1}{\tau - 1}
\]
(see Hardy and Wright\(^{(13)}\)). Expanding the expressions as power-series in $1/\tau$ and using the properties of $\phi$\(^{(13)}\) one proves the equality for all $\tau > 1$.

We want to stress the importance of lemma 5.3 in connection with this treatment of the function $R : \beta \mapsto \rho(\phi_{r,\beta})$. This lemma asserts that if we study maps $\psi_n$ such that
\[
\lim_{n \to \infty} \|\psi_n - \phi_{r,\beta}\| = 0
\]
in the $C^0$ topology, then $\psi_n$ has rotation interval $[\rho_{in}, \rho_{zn}]$ such that
\[
\lim_{n \to \infty} \rho_{in} = \lim_{n \to \infty} \rho_{zn} = \rho(\phi_{r,\beta}).
\]
In other words, we have a tool to estimate the rotation interval of an arbitrary mapping $\psi$ if it is close to $\phi_{r,\beta}$ for some $\tau$ and some $\beta$.

In recent papers the metric properties of the invariant set $\Sigma_p$ have been studied in a more general context\(^{(7,14)}\). For our piecewise linear mapping, lemma

\[
\beta = 1/3 = 1/(4 - 1).
\]
3.3 and 3.4 assert that the ordering of points of one orbit in $\Sigma_p$ is exactly the same as the ordering of points under rigid rotation $(d + k\rho) \mod 1$. The distances between a point and its iterates, however, are not preserved. In particular Kadanoff$^7$ and Sarkar$^{14}$ give expressions for the distance between $\alpha_p/\tau$ and its $Q_{2m}$th iterate under the map $\phi_{\tau,\alpha_p}$ with irrational rotation number $\rho$ ($\rho$ has continued fractions $q_n/Q_n$). Since in this paper we developed an explicit representation for the attracting set $\Sigma_\rho$, the conclusions of these two authors might be proven in the piecewise linear case.

In fact, for the two-parameter family $\phi_{\tau,\rho}$ and $\tau$ given we have constructed the function $R: \beta \rightarrow \rho(\phi_{\tau,\rho})$ explicitly. Let $\rho(\phi_{\tau,\rho}) = \rho$ for some given values of $\tau$ and $\beta$; for $q_{\tau,\rho}$ we have constructed the invariant attracting set: it is the set of optimal sequences with rotation number $\rho$ (as numbers on the base $\tau$ and modulo 1).

Acknowledgments

The author would like to thank Ben Wittner, Kevin Hockett, Mitchell Feigenbaum, Philip Holmes and Stellan Ostlund for their valuable ideas and discussions on the subject matter. This work was partially supported by NSF grant CME 84.
